1508

The diagram is

Observe that, if we let γ be the equator going through the midpoints of the edges 21, 04, 63, and 21, and we let C be the antipodal of the midpoint M of the edge 21, then a central symmetry with respect to C maps the quadrilateral 0412 into 3621, the point 0 in 3, and the equator γ bisecting 0 in the equator γ' bisecting 3. So the two intersections of γ and γ' (which cannot coincide because the angle in S is not π) are C and H

This is actually impossible because the bisector of a quadrilateral never

passes through the midpoint of the opposite edge. But it is also impossible because C would need to be S and the angle in S would need to be flat by the invariance under the symmetry.
